## Eigenvalue Problems

Eigenvalue problems occur in many areas of science and engineering, such as structural analysis

Eigenvalues also important in analyzing numerical methods

Theory and algorithms apply to complex matrices as well as real matrices

With complex matrices, use conjugate transpose,  $\mathbf{A}^H$ , instead of usual transpose,  $\mathbf{A}^T$

## Eigenvalues and Eigenvectors

Standard eigenvalue problem: Given  $n \times n$  matrix  $\mathbf{A}$ , find scalar  $\lambda$  and nonzero vector  $\mathbf{x}$  such that

$$\mathbf{A}\mathbf{x} = \lambda\mathbf{x}$$

$\lambda$  is *eigenvalue*, and  $\mathbf{x}$  is corresponding *eigenvector*

*Spectrum*  $= \lambda(\mathbf{A}) =$  set of eigenvalues of  $\mathbf{A}$

*Spectral radius*  $= \rho(\mathbf{A}) = \max\{|\lambda| : \lambda \in \lambda(\mathbf{A})\}$

## **Geometric Interpretation**

Matrix expands or shrinks any vector lying in direction of eigenvector by scalar factor

Expansion or contraction factor given by corresponding eigenvalue  $\lambda$

Eigenvalues and eigenvectors decompose complicated behavior of general linear transformation into simpler actions

## Examples: Eigenvalues and Eigenvectors

1.  $A = \begin{bmatrix} 1 & 0 \\ 0 & 2 \end{bmatrix}$ :

$$\lambda_1 = 1, \mathbf{x}_1 = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \quad \lambda_2 = 2, \mathbf{x}_2 = \begin{bmatrix} 0 \\ 1 \end{bmatrix}$$

2.  $A = \begin{bmatrix} 1 & 1 \\ 0 & 2 \end{bmatrix}$ :

$$\lambda_1 = 1, \mathbf{x}_1 = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \quad \lambda_2 = 2, \mathbf{x}_2 = \begin{bmatrix} 1 \\ 1 \end{bmatrix}$$

3.  $A = \begin{bmatrix} 3 & -1 \\ -1 & 3 \end{bmatrix}$ :

$$\lambda_1 = 2, \mathbf{x}_1 = \begin{bmatrix} 1 \\ 1 \end{bmatrix}, \quad \lambda_2 = 4, \mathbf{x}_2 = \begin{bmatrix} 1 \\ -1 \end{bmatrix}$$

## Examples Continued

$$4. \mathbf{A} = \begin{bmatrix} 1.5 & 0.5 \\ 0.5 & 1.5 \end{bmatrix}:$$

$$\lambda_1 = 2, \mathbf{x}_1 = \begin{bmatrix} 1 \\ 1 \end{bmatrix}, \quad \lambda_2 = 1, \mathbf{x}_2 = \begin{bmatrix} -1 \\ 1 \end{bmatrix}$$

$$5. \mathbf{A} = \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix}:$$

$$\lambda_1 = i, \mathbf{x}_1 = \begin{bmatrix} 1 \\ i \end{bmatrix}, \quad \lambda_2 = -i, \mathbf{x}_2 = \begin{bmatrix} i \\ 1 \end{bmatrix},$$

where  $i = \sqrt{-1}$

## Characteristic Polynomial

Equation  $Ax = \lambda x$  equivalent to

$$(A - \lambda I)x = o,$$

which has nonzero solution  $x$  if, and only if, its matrix is singular

Eigenvalues of  $A$  are roots  $\lambda_i$  of *characteristic polynomial*

$$\det(A - \lambda I) = 0$$

in  $\lambda$  of degree  $n$

*Fundamental Theorem of Algebra* implies that  $n \times n$  matrix  $A$  always has  $n$  eigenvalues, but they may be neither real nor distinct

Complex eigenvalues of real matrix occur in complex conjugate pairs: if  $\alpha + i\beta$  is eigenvalue of real matrix, then so is  $\alpha - i\beta$ , where  $i = \sqrt{-1}$

## Example: Characteristic Polynomial

Consider characteristic polynomial of previous example matrix:

$$\det \left( \begin{bmatrix} 3 & -1 \\ -1 & 3 \end{bmatrix} - \lambda \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \right) =$$

$$\det \left( \begin{bmatrix} 3 - \lambda & -1 \\ -1 & 3 - \lambda \end{bmatrix} \right) =$$

$$(3 - \lambda)(3 - \lambda) - (-1)(-1) = \lambda^2 - 6\lambda + 8 = 0,$$

so eigenvalues given by

$$\lambda = \frac{6 \pm \sqrt{36 - 32}}{2},$$

or

$$\lambda_1 = 2, \quad \lambda_2 = 4$$

## Companion Matrix

Monic polynomial

$$p(\lambda) = c_0 + c_1\lambda + \cdots + c_{n-1}\lambda^{n-1} + \lambda^n$$

characteristic polynomial of *companion matrix*

$$C_n = \begin{bmatrix} 0 & 0 & \cdots & 0 & -c_0 \\ 1 & 0 & \cdots & 0 & -c_1 \\ 0 & 1 & \cdots & 0 & -c_2 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 1 & -c_{n-1} \end{bmatrix}$$

Roots of polynomial of degree  $> 4$  cannot always be computed in finite number of steps

So in general, computation of eigenvalues of matrices of order  $> 4$  requires (theoretically infinite) iterative process

## Characteristic Polynomial, cont.

Computing eigenvalues using characteristic polynomial *not* recommended because

- work in computing coefficients of characteristic polynomial
- coefficients of characteristic polynomial sensitive
- work in solving for roots of characteristic polynomial

Characteristic polynomial powerful theoretical tool but usually not useful computationally

## Example: Characteristic Polynomial

Consider

$$\mathbf{A} = \begin{bmatrix} 1 & \epsilon \\ \epsilon & 1 \end{bmatrix},$$

where  $\epsilon$  is positive number slightly smaller than  $\sqrt{\epsilon_{\text{mach}}}$

Exact eigenvalues of  $\mathbf{A}$  are  $1 + \epsilon$  and  $1 - \epsilon$

Computing characteristic polynomial in floating-point arithmetic,

$$\det(\mathbf{A} - \lambda \mathbf{I}) = \lambda^2 - 2\lambda + (1 - \epsilon^2) = \lambda^2 - 2\lambda + 1,$$

which has 1 as double root

Thus, cannot resolve eigenvalues by this method even though they are distinct in working precision

## Multiplicity and Diagonalizability

*Multiplicity* is number of times root appears when polynomial written as product of linear factors

Eigenvalue of multiplicity 1 is *simple*

*Defective* matrix has eigenvalue of multiplicity  $k > 1$  with fewer than  $k$  linearly independent corresponding eigenvectors

Nondefective matrix  $A$  has  $n$  linearly independent eigenvectors, so is *diagonalizable*:

$$X^{-1}AX = D,$$

where  $X$  is nonsingular matrix of eigenvectors

## Eigenspaces and Invariant Subspaces

Eigenvectors can be scaled arbitrarily: if  $\mathbf{A}\mathbf{x} = \lambda\mathbf{x}$ , then  $\mathbf{A}(\gamma\mathbf{x}) = \lambda(\gamma\mathbf{x})$  for any scalar  $\gamma$ , so  $\gamma\mathbf{x}$  is also eigenvector corresponding to  $\lambda$

Eigenvectors usually *normalized* by requiring some norm of eigenvector to be 1

$$\text{Eigenspace} = \mathcal{S}_\lambda = \{\mathbf{x} : \mathbf{A}\mathbf{x} = \lambda\mathbf{x}\}$$

Subspace  $\mathcal{S}$  of  $\mathbb{R}^n$  (or  $\mathbb{C}^n$ ) *invariant* if  $\mathbf{A}\mathcal{S} \subseteq \mathcal{S}$

For eigenvectors  $\mathbf{x}_1 \cdots \mathbf{x}_p$ ,  $\text{span}([\mathbf{x}_1 \cdots \mathbf{x}_p])$  is invariant subspace

## Properties of Matrices

Matrix properties relevant to eigenvalue problems

Property	Definition
Diagonal	$a_{ij} = 0$ for $i \neq j$
Tridiagonal	$a_{ij} = 0$ for $ i - j  > 1$
Triangular	$a_{ij} = 0$ for $i > j$ (upper) $a_{ij} = 0$ for $i < j$ (lower)
Hessenberg	$a_{ij} = 0$ for $i > j + 1$ (upper) $a_{ij} = 0$ for $i < j - 1$ (lower)
Orthogonal	$\mathbf{A}^T \mathbf{A} = \mathbf{A} \mathbf{A}^T = \mathbf{I}$
Unitary	$\mathbf{A}^H \mathbf{A} = \mathbf{A} \mathbf{A}^H = \mathbf{I}$
Symmetric	$\mathbf{A} = \mathbf{A}^T$
Hermitian	$\mathbf{A} = \mathbf{A}^H$
Normal	$\mathbf{A}^H \mathbf{A} = \mathbf{A} \mathbf{A}^H$

## Examples: Matrix Properties

Transpose:

$$\begin{bmatrix} 1 & 2 \\ 3 & 4 \end{bmatrix}^T = \begin{bmatrix} 1 & 3 \\ 2 & 4 \end{bmatrix}$$

Conjugate transpose:

$$\begin{bmatrix} 1 + i & 1 + 2i \\ 2 - i & 2 - 2i \end{bmatrix}^H = \begin{bmatrix} 1 - i & 2 + i \\ 1 - 2i & 2 + 2i \end{bmatrix}$$

Symmetric:

$$\begin{bmatrix} 1 & 2 \\ 2 & 3 \end{bmatrix}$$

Nonsymmetric:

$$\begin{bmatrix} 1 & 3 \\ 2 & 4 \end{bmatrix}$$

## Examples Continued

Hermitian:

$$\begin{bmatrix} 1 & 1+i \\ 1-i & 2 \end{bmatrix}$$

NonHermitian:

$$\begin{bmatrix} 1 & 1+i \\ 1+i & 2 \end{bmatrix}$$

Orthogonal:

$$\begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \begin{bmatrix} -1 & 0 \\ 0 & -1 \end{bmatrix}, \begin{bmatrix} \sqrt{2}/2 & \sqrt{2}/2 \\ -\sqrt{2}/2 & \sqrt{2}/2 \end{bmatrix}$$

Unitary:

$$\begin{bmatrix} i\sqrt{2}/2 & \sqrt{2}/2 \\ -\sqrt{2}/2 & -i\sqrt{2}/2 \end{bmatrix}$$

Nonorthogonal:

$$\begin{bmatrix} 1 & 1 \\ 1 & 2 \end{bmatrix}$$

## Examples Continued

Normal:

$$\begin{bmatrix} 1 & 2 & 0 \\ 0 & 1 & 2 \\ 2 & 0 & 1 \end{bmatrix}$$

Nonnormal:

$$\begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}$$

## Properties of Eigenvalue Problems

Properties of eigenvalue problem affecting choice of algorithm and software

- Are all of eigenvalues needed, or only a few?
- Are only eigenvalues needed, or are corresponding eigenvectors also needed?
- Is matrix real or complex?
- Is matrix relatively small and dense, or large and sparse?
- Does matrix have any special properties, such as symmetry, or is it general matrix?

## Conditioning of Eigenvalue Problems

Condition of eigenvalue problem is sensitivity of eigenvalues and eigenvectors to changes in matrix

Conditioning of eigenvalue problem *not* same as conditioning of solution to linear system for same matrix

Different eigenvalues and eigenvectors not necessarily equally sensitive to perturbations in matrix

## Conditioning of Eigenvalues

If  $\mu$  is eigenvalue of perturbation  $\mathbf{A} + \mathbf{E}$  of non-defective matrix  $\mathbf{A}$ , then

$$|\mu - \lambda_k| \leq \text{cond}_2(\mathbf{X}) \|\mathbf{E}\|_2,$$

where  $\lambda_k$  is closest eigenvalue of  $\mathbf{A}$  to  $\mu$  and  $\mathbf{X}$  is nonsingular matrix of eigenvectors of  $\mathbf{A}$

Absolute condition number of eigenvalues is condition number of matrix of eigenvectors with respect to solving linear equations

Eigenvalues may be sensitive if eigenvectors nearly linearly dependent (i.e., matrix nearly defective)

For *normal* matrix ( $\mathbf{A}^H \mathbf{A} = \mathbf{A} \mathbf{A}^H$ ), eigenvectors orthogonal, so eigenvalues well-conditioned

## Conditioning of Eigenvalue

If

$$(A + E)(x + \Delta x) = (\lambda + \Delta\lambda)(x + \Delta x),$$

where  $\lambda$  is simple eigenvalue of  $A$ , then

$$|\Delta\lambda| \lesssim \frac{\|y\|_2 \cdot \|x\|_2}{|y^H x|} \|E\|_2 = \frac{1}{\cos(\theta)} \|E\|_2,$$

where  $x$  and  $y$  are corresponding right and left eigenvectors and  $\theta$  is angle between them

For symmetric or Hermitian matrix, right and left eigenvectors are same, so  $\cos(\theta) = 1$  and eigenvalues inherently well-conditioned

Eigenvalues of nonnormal matrices may be sensitive

For multiple or closely clustered eigenvalues, corresponding eigenvectors may be sensitive

## Problem Transformations

**Shift:** If  $Ax = \lambda x$  and  $\sigma$  is any scalar, then  $(A - \sigma I)x = (\lambda - \sigma)x$ , so eigenvalues of shifted matrix are shifted eigenvalues of original matrix

**Inversion:** If  $A$  is nonsingular and  $Ax = \lambda x$  with  $x \neq 0$ , then  $\lambda \neq 0$  and  $A^{-1}x = (1/\lambda)x$ , so eigenvalues of inverse are reciprocals of eigenvalues of original matrix

**Powers:** If  $Ax = \lambda x$ , then  $A^k x = \lambda^k x$ , so eigenvalues of power of matrix are same power of eigenvalues of original matrix

**Polynomial:** If  $Ax = \lambda x$  and  $p(t)$  is polynomial, then  $p(A)x = p(\lambda)x$ , so eigenvalues of polynomial in matrix are values of polynomial evaluated at eigenvalues of original matrix

## Similarity Transformation

$B$  is *similar* to  $A$  if there is nonsingular  $T$  such that

$$B = T^{-1}AT$$

Then

$$By = \lambda y \Rightarrow T^{-1}ATy = \lambda y \Rightarrow A(Ty) = \lambda(Ty),$$

so  $A$  and  $B$  have same eigenvalues, and if  $y$  is eigenvector of  $B$ , then  $x = Ty$  is eigenvector of  $A$

Similarity transformations preserve eigenvalues and eigenvectors easily recovered

### Example: Similarity Transformation

From eigenvalues and eigenvectors for previous example,

$$\begin{bmatrix} 3 & -1 \\ -1 & 3 \end{bmatrix} \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix} = \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix} \begin{bmatrix} 2 & 0 \\ 0 & 4 \end{bmatrix},$$

and hence

$$\begin{bmatrix} 0.5 & 0.5 \\ 0.5 & -0.5 \end{bmatrix} \begin{bmatrix} 3 & -1 \\ -1 & 3 \end{bmatrix} \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix} = \begin{bmatrix} 2 & 0 \\ 0 & 4 \end{bmatrix},$$

so original matrix is similar to diagonal matrix, and eigenvectors form columns of similarity transformation matrix

## Diagonal Form

Eigenvalues of diagonal matrix are diagonal entries, and eigenvectors are columns of identity matrix

Diagonal form desirable in simplifying eigenvalue problems for general matrices by similarity transformations

But not all matrices diagonalizable by similarity transformation

Closest can get, in general, is *Jordan form*, which is nearly diagonal but may have some nonzero entries on first superdiagonal, corresponding to one or more multiple eigenvalues

## Triangular Form

Any matrix can be transformed into triangular (*Schur*) form by similarity, and eigenvalues of triangular matrix are diagonal entries

Eigenvectors of triangular matrix less obvious, but still straightforward to compute

If

$$A - \lambda I = \begin{bmatrix} U_{11} & u & U_{13} \\ o & 0 & v^T \\ O & o & U_{33} \end{bmatrix}$$

is triangular, then  $U_{11}y = u$  can be solved for  $y$ , so that

$$x = \begin{bmatrix} y \\ -1 \\ o \end{bmatrix}$$

is corresponding eigenvector

## Block Triangular Form

If

$$A = \begin{bmatrix} A_{11} & A_{12} & \cdots & A_{1p} \\ & A_{22} & \cdots & A_{2p} \\ & & \ddots & \vdots \\ & & & A_{pp} \end{bmatrix},$$

with *square* diagonal blocks, then

$$\lambda(A) = \bigcup_{j=1}^p \lambda(A_{jj}),$$

so eigenvalue problem breaks into  $p$  smaller eigenvalue problems

Real Schur form has  $1 \times 1$  diagonal blocks corresponding to real eigenvalues and  $2 \times 2$  diagonal blocks corresponding to pairs of complex conjugate eigenvalues

## Forms Attainable by Similarity

$A$	$T$	$B$
distinct eigenvalues	nonsingular	diagonal
real symmetric	orthogonal	real diagonal
complex Hermitian	unitary	real diagonal
normal	unitary	diagonal
arbitrary real	orthogonal	real block triangular (real Schur)
arbitrary	unitary	upper triangular (Schur)
arbitrary	nonsingular	almost diagonal (Jordan)

Given matrix  $A$  with indicated property, matrices  $B$  and  $T$  exist with indicated properties such that  $B = T^{-1}AT$

When  $B$  is diagonal or triangular, its diagonal entries are eigenvalues

When  $B$  is diagonal, columns of  $T$  are eigenvectors

## Power Iteration

Simplest method for computing one eigenvalue-eigenvector pair is *power iteration*, which repeatedly multiplies matrix times initial starting vector

Assume  $A$  has unique eigenvalue of maximum modulus, say  $\lambda_1$ , with corresponding eigenvector  $v_1$

Then, starting from nonzero vector  $x_0$ , iteration scheme

$$x_k = Ax_{k-1}$$

converges to multiple of eigenvector  $v_1$  corresponding to dominant eigenvalue  $\lambda_1$

## Convergence of Power Iteration

To see why power iteration converges to dominant eigenvector, express starting vector  $x_0$  as linear combination

$$x_0 = \sum_{i=1}^n \alpha_i v_i,$$

where  $v_i$  are eigenvectors of  $A$

Then

$$\begin{aligned} x_k &= Ax_{k-1} = A^2x_{k-2} = \cdots = A^kx_0 = \\ &\sum_{i=1}^n \lambda_i^k \alpha_i v_i = \lambda_1^k \left( \alpha_1 v_1 + \sum_{i=2}^n (\lambda_i/\lambda_1)^k \alpha_i v_i \right) \end{aligned}$$

Since  $|\lambda_i/\lambda_1| < 1$  for  $i > 1$ , successively higher powers go to zero, leaving only component corresponding to  $v_1$

## Example: Power Iteration

Ratio of values of given component of  $x_k$  from one iteration to next converges to dominant eigenvalue  $\lambda_1$

For example, if  $A = \begin{bmatrix} 1.5 & 0.5 \\ 0.5 & 1.5 \end{bmatrix}$  and  $x_0 = \begin{bmatrix} 0 \\ 1 \end{bmatrix}$ , we obtain sequence

$k$	$x_k^T$		ratio
0	0.0	1.0	
1	0.5	1.5	1.500
2	1.5	2.5	1.667
3	3.5	4.5	1.800
4	7.5	8.5	1.889
5	15.5	16.5	1.941
6	31.5	32.5	1.970
7	63.5	64.5	1.985
8	127.5	128.5	1.992

Ratio for each component is converging to dominant eigenvalue, which is 2

## Limitations of Power Iteration

Power iteration can fail for various reasons:

- Starting vector may have *no* component in dominant eigenvector  $v_1$  (i.e.,  $\alpha_1 = 0$ ) — not problem in practice because rounding error usually introduces such component in any case
- There may be more than one eigenvalue having same (maximum) modulus, in which case iteration may converge to linear combination of corresponding eigenvectors
- For real matrix and starting vector, iteration can never converge to complex vector

## Normalized Power Iteration

Geometric growth of components at each iteration risks eventual overflow (or underflow if  $\lambda_1 < 1$ )

Approximate eigenvector should be normalized at each iteration, say, by requiring its largest component to be 1 in modulus, giving iteration scheme

$$\mathbf{y}_k = \mathbf{A}\mathbf{x}_{k-1},$$

$$\mathbf{x}_k = \mathbf{y}_k / \|\mathbf{y}_k\|_\infty$$

With normalization,  $\|\mathbf{y}_k\|_\infty \rightarrow |\lambda_1|$ , and  $\mathbf{x}_k \rightarrow \mathbf{v}_1 / \|\mathbf{v}_1\|_\infty$

## Example: Normalized Power Iteration

Repeating previous example with normalized scheme,

$k$	$\mathbf{x}_k^T$		$\ \mathbf{y}_k\ _\infty$
0	0.000	1.0	
1	0.333	1.0	1.500
2	0.600	1.0	1.667
3	0.778	1.0	1.800
4	0.882	1.0	1.889
5	0.939	1.0	1.941
6	0.969	1.0	1.970
7	0.984	1.0	1.985
8	0.992	1.0	1.992

## Geometric Interpretation

Behavior of power iteration depicted geometrically:

Initial vector

$$x_0 = \begin{bmatrix} 0 \\ 1 \end{bmatrix} = 1 \begin{bmatrix} 1 \\ 1 \end{bmatrix} + 1 \begin{bmatrix} -1 \\ 1 \end{bmatrix}$$

contains equal components in two eigenvectors (shown by dashed arrows)

Repeated multiplication by  $\mathbf{A}$  causes component in first eigenvector (corresponding to larger eigenvalue, 2) to dominate, and hence sequence of vectors converges to that eigenvector

## Power Iteration with Shift

Convergence rate of power iteration depends on ratio  $|\lambda_2/\lambda_1|$ , where  $\lambda_2$  is eigenvalue having second largest modulus

May be possible to choose shift,  $A - \sigma I$ , such that

$$\left| \frac{\lambda_2 - \sigma}{\lambda_1 - \sigma} \right| < \left| \frac{\lambda_2}{\lambda_1} \right|,$$

so convergence is accelerated

Shift must then be added to result to obtain eigenvalue of original matrix

## **Example: Power Iteration with Shift**

In earlier example, for instance, if we pick shift of  $\sigma = 1$ , (which is equal to other eigenvalue) then ratio becomes zero and method converges in one iteration

In general, we would not be able to make such fortuitous choice, but shifts can still be extremely useful in some contexts, as we will see later

## Inverse Iteration

If smallest eigenvalue of matrix required rather than largest, can make use of fact that eigenvalues of  $\mathbf{A}^{-1}$  are reciprocals of those of  $\mathbf{A}$ , so smallest eigenvalue of  $\mathbf{A}$  is reciprocal of largest eigenvalue of  $\mathbf{A}^{-1}$

This leads to *inverse iteration* scheme

$$\mathbf{A}\mathbf{y}_k = \mathbf{x}_{k-1},$$

$$\mathbf{x}_k = \mathbf{y}_k / \|\mathbf{y}_k\|_\infty,$$

which is equivalent to power iteration applied to  $\mathbf{A}^{-1}$

Inverse of  $\mathbf{A}$  not computed explicitly, but factorization of  $\mathbf{A}$  used to solve system of linear equations at each iteration

## Inverse Iteration, continued

Inverse iteration converges to eigenvector corresponding to smallest eigenvalue of  $A$

Eigenvalue obtained is dominant eigenvalue of  $A^{-1}$ , and hence its reciprocal is smallest eigenvalue of  $A$  in modulus

## Example: Inverse Iteration

Applying inverse iteration to previous example to compute smallest eigenvalue yields sequence

$k$	$\mathbf{x}_k^T$		$\ \mathbf{y}_k\ _\infty$
0	0.000	1.0	
1	-0.333	1.0	0.750
2	-0.600	1.0	0.833
3	-0.778	1.0	0.900
4	-0.882	1.0	0.944
5	-0.939	1.0	0.971
6	-0.969	1.0	0.985

which is indeed converging to 1 (which is its own reciprocal in this case)

## Inverse Iteration with Shift

As before, shifting strategy, working with  $\mathbf{A} - \sigma \mathbf{I}$  for some scalar  $\sigma$ , can greatly improve convergence

Inverse iteration particularly useful for computing eigenvector corresponding to approximate eigenvalue, since it converges rapidly when applied to shifted matrix  $\mathbf{A} - \lambda \mathbf{I}$ , where  $\lambda$  is approximate eigenvalue

Inverse iteration also useful for computing eigenvalue closest to given value  $\beta$ , since if  $\beta$  is used as shift, then desired eigenvalue corresponds to smallest eigenvalue of shifted matrix

## Rayleigh Quotient

Given approximate eigenvector  $x$  for real matrix  $A$ , determining best estimate for corresponding eigenvalue  $\lambda$  can be considered as  $n \times 1$  linear least squares approximation problem

$$x\lambda \cong Ax$$

From normal equation  $x^T x \lambda = x^T Ax$ , least squares solution is given by

$$\lambda = \frac{x^T Ax}{x^T x}$$

This quantity, known as *Rayleigh quotient*, has many useful properties

## Example: Rayleigh Quotient

Rayleigh quotient can accelerate convergence of iterative methods such as power iteration, since Rayleigh quotient  $\mathbf{x}_k^T \mathbf{A} \mathbf{x}_k / \mathbf{x}_k^T \mathbf{x}_k$  gives better approximation to eigenvalue at iteration  $k$  than does basic method alone

For previous example using power iteration, value of Rayleigh quotient at each iteration is shown below

$k$	$\mathbf{x}_k^T$		$\ \mathbf{y}_k\ _\infty$	$\mathbf{x}_k^T \mathbf{A} \mathbf{x}_k / \mathbf{x}_k^T \mathbf{x}_k$
0	0.000	1.0		
1	0.333	1.0	1.500	1.500
2	0.600	1.0	1.667	1.800
3	0.778	1.0	1.800	1.941
4	0.882	1.0	1.889	1.985
5	0.939	1.0	1.941	1.996
6	0.969	1.0	1.970	1.999

## Rayleigh Quotient Iteration

Given approximate eigenvector, Rayleigh quotient yields good estimate for corresponding eigenvalue

Conversely, inverse iteration converges rapidly to eigenvector if approximate eigenvalue is used as shift, with one iteration often sufficing

These two ideas combined in *Rayleigh quotient iteration*

$$\sigma_k = \mathbf{x}_k^T \mathbf{A} \mathbf{x}_k / \mathbf{x}_k^T \mathbf{x}_k,$$

$$(\mathbf{A} - \sigma_k \mathbf{I}) \mathbf{y}_{k+1} = \mathbf{x}_k,$$

$$\mathbf{x}_{k+1} = \mathbf{y}_{k+1} / \|\mathbf{y}_{k+1}\|_\infty,$$

starting from given nonzero vector  $\mathbf{x}_0$

Scheme especially effective for symmetric matrices and usually converges very rapidly

## Rayleigh Quotient Iteration, cont.

Using different shift at each iteration means matrix must be refactored each time to solve linear system, so cost per iteration is high unless matrix has special form that makes factorization easy

Same idea also works for complex matrices, for which transpose is replaced by conjugate transpose, so Rayleigh quotient becomes  $x^H A x / x^H x$

## Example: Rayleigh Quotient Iteration

Using same matrix as previous examples and randomly chosen starting vector  $x_0$ , Rayleigh quotient iteration converges in two iterations:

$k$	$x_k^T$		$\sigma_k$
0	0.807	0.397	1.896
1	0.924	1.000	1.998
2	1.000	1.000	2.000

## Deflation

After eigenvalue  $\lambda_1$  and corresponding eigenvector  $\mathbf{x}_1$  have been computed, then additional eigenvalues  $\lambda_2, \dots, \lambda_n$  of  $\mathbf{A}$  can be computed by *deflation*, which effectively removes known eigenvalue

Let  $\mathbf{H}$  be any nonsingular matrix such that  $\mathbf{H}\mathbf{x}_1 = \alpha\mathbf{e}_1$ , scalar multiple of first column of identity matrix (Householder transformation good choice for  $\mathbf{H}$ )

Then similarity transformation determined by  $\mathbf{H}$  transforms  $\mathbf{A}$  into form

$$\mathbf{H}\mathbf{A}\mathbf{H}^{-1} = \begin{bmatrix} \lambda_1 & \mathbf{b}^T \\ \mathbf{o} & \mathbf{B} \end{bmatrix},$$

where  $\mathbf{B}$  is matrix of order  $n - 1$  having eigenvalues  $\lambda_2, \dots, \lambda_n$

## Deflation, continued

Thus, we can work with  $\mathbf{B}$  to compute next eigenvalue  $\lambda_2$

Moreover, if  $\mathbf{y}_2$  is eigenvector of  $\mathbf{B}$  corresponding to  $\lambda_2$ , then

$$\mathbf{x}_2 = \mathbf{H}^{-1} \begin{bmatrix} \alpha \\ \mathbf{y}_2 \end{bmatrix}, \quad \text{where} \quad \alpha = \frac{\mathbf{b}^T \mathbf{y}_2}{\lambda_2 - \lambda_1},$$

is eigenvector corresponding to  $\lambda_2$  for original matrix  $\mathbf{A}$ , provided  $\lambda_1 \neq \lambda_2$

Process can be repeated to find additional eigenvalues and eigenvectors

## Deflation, continued

Alternative approach lets  $u_1$  be any vector such that  $u_1^T x_1 = \lambda_1$

Then  $A - x_1 u_1^T$  has eigenvalues  $0, \lambda_2, \dots, \lambda_n$

Possible choices for  $u_1$  include

- $u_1 = \lambda_1 x_1$ , if  $A$  symmetric and  $x_1$  normalized so that  $\|x_1\|_2 = 1$ ,
- $u_1 = \lambda_1 y_1$ , where  $y_1$  is corresponding left eigenvector (i.e.,  $A^T y_1 = \lambda_1 y_1$ ) normalized so that  $y_1^T x_1 = 1$ ,
- $u_1 = A^T e_k$ , if  $x_1$  normalized so that  $\|x_1\|_\infty = 1$  and  $k$ th component of  $x_1$  is 1

## Simultaneous Iteration

Simplest method for computing many eigenvalue-eigenvector pairs is *simultaneous iteration*, which repeatedly multiplies matrix times matrix of initial starting vectors

Starting from  $n \times p$  matrix  $\mathbf{X}_0$  of rank  $p$ , iteration scheme is

$$\mathbf{X}_k = \mathbf{A}\mathbf{X}_{k-1}$$

$\text{span}(\mathbf{X}_k)$  converges to invariant subspace determined by  $p$  largest eigenvalues of  $\mathbf{A}$ , provided  $|\lambda_p| > |\lambda_{p+1}|$

Also called *subspace iteration*

## Orthogonal Iteration

As with power iteration, normalization needed with simultaneous iteration

Each column of  $\mathbf{X}_k$  converges to dominant eigenvector, so columns of  $\mathbf{X}_k$  become increasingly ill-conditioned basis for  $\text{span}(\mathbf{X}_k)$

Both issues addressed by computing QR factorization at each iteration:

$$\hat{\mathbf{Q}}_k \mathbf{R}_k = \mathbf{X}_{k-1},$$

$$\mathbf{X}_k = \mathbf{A} \hat{\mathbf{Q}}_k$$

where  $\hat{\mathbf{Q}}_k \mathbf{R}_k$  is *reduced* QR factorization of  $\mathbf{X}_{k-1}$

Iteration converges to block triangular form, and leading block is triangular if moduli of consecutive eigenvalues are distinct

## QR Iteration

For  $p = n$  and  $X_0 = I$ , matrices

$$A_k = \hat{Q}_k^H A \hat{Q}_k,$$

generated by orthogonal iteration converge to triangular or block triangular form, yielding all eigenvalues of  $A$

*QR iteration* computes successive matrices  $A_k$  without forming above product explicitly

Starting with  $A_0 = A$ , at iteration  $k$  compute QR factorization

$$Q_k R_k = A_{k-1}$$

and form reverse product

$$A_k = R_k Q_k$$

Since

$$A_k = R_k Q_k = Q_k^H A_{k-1} Q_k,$$

successive matrices  $A_k$  unitarily similar to each other

## QR Iteration, continued

Diagonal entries (or eigenvalues of diagonal blocks) of  $A_k$  converge to eigenvalues of  $A$

Product of orthogonal matrices  $Q_k$  converges to matrix of corresponding eigenvectors

If  $A$  symmetric, then symmetry preserved by QR iteration, so  $A_k$  converge to matrix that is both triangular and symmetric, hence diagonal

## Example: QR Iteration

Let  $A_0 = \begin{bmatrix} 7 & 2 \\ 2 & 4 \end{bmatrix}$

Compute QR factorization

$$A_0 = Q_1 R_1 = \begin{bmatrix} .962 & -.275 \\ .275 & .962 \end{bmatrix} \begin{bmatrix} 7.28 & 3.02 \\ 0 & 3.30 \end{bmatrix}$$

and form reverse product

$$A_1 = R_1 Q_1 = \begin{bmatrix} 7.83 & .906 \\ .906 & 3.17 \end{bmatrix}$$

Off-diagonal entries now smaller, and diagonal entries closer to eigenvalues, 8 and 3

Process continues until matrix within tolerance of being diagonal, and diagonal entries then closely approximate eigenvalues

## QR Iteration with Shifts

Convergence rate of QR iteration accelerated by incorporating *shifts*:

$$Q_k R_k = A_{k-1} - \sigma_k I,$$

$$A_k = R_k Q_k + \sigma_k I,$$

where  $\sigma_k$  is rough approximation to eigenvalue

Good shift can be determined by computing eigenvalues of  $2 \times 2$  submatrix in lower right corner of matrix

## Example: QR Iteration with Shifts

Repeat previous example, but with shift of  $\sigma_0 = 4$ , which is lower right corner entry of matrix

We compute QR factorization

$$A_0 - \sigma_1 I = Q_1 R_1 = \begin{bmatrix} .832 & .555 \\ .555 & -.832 \end{bmatrix} \begin{bmatrix} 3.61 & 1.66 \\ 0 & 1.11 \end{bmatrix}$$

and form reverse product, adding back shift to obtain

$$A_1 = R_1 Q_1 + \sigma_1 I = \begin{bmatrix} 7.92 & .615 \\ .615 & 3.08 \end{bmatrix}$$

After one iteration, off-diagonal entries smaller compared with unshifted algorithm, and eigenvalues closer approximations to eigenvalues

## Preliminary Reduction

Efficiency of QR iteration enhanced by first transforming matrix as close to triangular form as possible before beginning iterations

*Hessenberg matrix* is triangular except for one additional nonzero diagonal immediately adjacent to main diagonal

Any matrix can be reduced to Hessenberg form in finite number of steps by orthogonal similarity transformation, for example using Householder transformations

Symmetric Hessenberg matrix is tridiagonal

Hessenberg or tridiagonal form preserved during successive QR iterations

## Preliminary Reduction, continued

Advantages of initial reduction to upper Hessenberg or tridiagonal form:

- Work per QR iteration reduced from  $\mathcal{O}(n^3)$  to  $\mathcal{O}(n^2)$  for general matrix or  $\mathcal{O}(n)$  for symmetric matrix
- Fewer QR iterations required because matrix nearly triangular (or diagonal) already
- If any zero entries on first subdiagonal, then matrix block triangular and problem can be broken into two or more smaller subproblems

## Preliminary Reduction, continued

QR iteration implemented in two-stages:

symmetric  $\longrightarrow$  tridiagonal  $\longrightarrow$  diagonal

or

general  $\longrightarrow$  Hessenberg  $\longrightarrow$  triangular

Preliminary reduction requires definite number of steps, whereas subsequent iterative stage continues until convergence

In practice only modest number of iterations usually required, so much of work is in preliminary reduction

Cost of accumulating eigenvectors, if needed, dominates total cost

## Cost of QR Iteration

Approximate overall cost of preliminary reduction and QR iteration, counting both additions and multiplications:

Symmetric matrices:

- $\frac{4}{3}n^3$  for eigenvalues only
- $9n^3$  for eigenvalues and eigenvectors

General matrices:

- $10n^3$  for eigenvalues only
- $25n^3$  for eigenvalues and eigenvectors

## Krylov Subspace Methods

Krylov subspace methods reduce matrix to Hessenberg (or tridiagonal) form using only matrix-vector multiplication

For arbitrary starting vector  $x_0$ , if

$$K_k = [x_0 \quad Ax_0 \quad \cdots \quad A^{k-1}x_0],$$

then

$$K_n^{-1}AK_n = C_n,$$

where  $C_n$  is upper Hessenberg (in fact, companion matrix)

To obtain better conditioned basis for  $\text{span}(K_n)$ , compute QR factorization

$$Q_n R_n = K_n,$$

so that

$$Q_n^H A Q_n = R_n C_n R_n^{-1} \equiv H,$$

with  $H$  upper Hessenberg

## Krylov Subspace Methods

Equating  $k$ th columns on each side of equation  $\mathbf{A}\mathbf{Q}_n = \mathbf{Q}_n\mathbf{H}$  yields recurrence

$$\mathbf{A}\mathbf{q}_k = h_{1k}\mathbf{q}_1 + \cdots + h_{kk}\mathbf{q}_k + h_{k+1,k}\mathbf{q}_{k+1}$$

relating  $\mathbf{q}_{k+1}$  to preceding vectors  $\mathbf{q}_1, \dots, \mathbf{q}_k$

Premultiplying by  $\mathbf{q}_j^H$  and using orthonormality,

$$h_{jk} = \mathbf{q}_j^H \mathbf{A}\mathbf{q}_k, \quad j = 1, \dots, k$$

These relationships yield Arnoldi iteration, which produces unitary matrix  $\mathbf{Q}_n$  and upper Hessenberg matrix  $\mathbf{H}_n$  column by column using only matrix-vector multiplication by  $\mathbf{A}$  and inner products of vectors

## Arnoldi Iteration

$x_0$  = arbitrary nonzero starting vector

$$q_1 = x_0 / \|x_0\|_2$$

**for**  $k = 1, 2, \dots$

$$u_k = Aq_k$$

**for**  $j = 1$  **to**  $k$

$$h_{jk} = q_j^H u_k$$

$$u_k = u_k - h_{jk} q_j$$

**end**

$$h_{k+1,k} = \|u_k\|_2$$

**if**  $h_{k+1,k} = 0$  **then** stop

$$q_{k+1} = u_k / h_{k+1,k}$$

**end**

## Arnoldi Iteration, continued

If

$$Q_k = [q_1 \quad \cdots \quad q_k],$$

then

$$H_k = Q_k^H A Q_k$$

is upper Hessenberg matrix

Eigenvalues of  $H_k$ , called *Ritz values*, are approximate eigenvalues of  $A$ , and *Ritz vectors* given by  $Q_k y$ , where  $y$  is eigenvector of  $H_k$ , are corresponding approximate eigenvectors of  $A$

Eigenvalues of  $H_k$  must be computed by another method, such as QR iteration, but this is easier problem if  $k \ll n$

## Arnoldi Iteration, continued

Arnoldi iteration fairly expensive in work and storage because each new vector  $q_k$  must be orthogonalized against all previous columns of  $Q_k$ , and all must be stored for that purpose.

So Arnoldi process usually restarted periodically with carefully chosen starting vector

Ritz values and vectors produced are often good approximations to eigenvalues and eigenvectors of  $A$  after relatively few iterations

## Lanczos Iteration

Work and storage costs drop dramatically if matrix symmetric or Hermitian, since recurrence then has only three terms and  $\mathbf{H}_k$  is tridiagonal (so usually denoted  $\mathbf{T}_k$ ), yielding Lanczos iteration

```
 $\mathbf{q}_0 = \mathbf{o}$   
 $\beta_0 = 0$   
 $\mathbf{x}_0 =$  arbitrary nonzero starting vector  
 $\mathbf{q}_1 = \mathbf{x}_0 / \|\mathbf{x}_0\|_2$   
for  $k = 1, 2, \dots$   
     $\mathbf{u}_k = \mathbf{A}\mathbf{q}_k$   
     $\alpha_k = \mathbf{q}_k^H \mathbf{u}_k$   
     $\mathbf{u}_k = \mathbf{u}_k - \beta_{k-1} \mathbf{q}_{k-1} - \alpha_k \mathbf{q}_k$   
     $\beta_k = \|\mathbf{u}_k\|_2$   
    if  $\beta_k = 0$  then stop  
     $\mathbf{q}_{k+1} = \mathbf{u}_k / \beta_k$   
end
```

## Lanczos Iteration, continued

$\alpha_k$  and  $\beta_k$  are diagonal and subdiagonal entries of symmetric tridiagonal matrix  $\mathbf{T}_k$

As with Arnoldi, Lanczos iteration does not produce eigenvalues and eigenvectors directly, but only tridiagonal matrix  $\mathbf{T}_k$ , whose eigenvalues and eigenvectors must be computed by another method to obtain Ritz values and vectors

If  $\beta_k = 0$ , then algorithm appears to break down, but in that case invariant subspace has already been identified (i.e., Ritz values and vectors are already exact at that point)

## Lanczos Iteration, continued

In principle, if Lanczos algorithm were run until  $k = n$ , resulting tridiagonal matrix would be orthogonally similar to  $A$

In practice, rounding error causes loss of orthogonality, invalidating this expectation

Problem can be overcome by reorthogonalizing vectors as needed, but expense can be substantial

Alternatively, can ignore problem, in which case algorithm still produces good eigenvalue approximations, but multiple copies of some eigenvalues may be generated

## Krylov Subspace Methods, continued

Great virtue of Arnoldi and Lanczos iterations is ability to produce good approximations to extreme eigenvalues for  $k \ll n$

Moreover, they require only one matrix-vector multiplication by  $A$  per step and little auxiliary storage, so are ideally suited to large sparse matrices

If eigenvalues are needed in middle of spectrum, say near  $\sigma$ , then algorithm can be applied to matrix  $(A - \sigma I)^{-1}$ , assuming it is practical to solve systems of form  $(A - \sigma I)x = y$

## Example: Lanczos Iteration

For  $29 \times 29$  symmetric matrix with eigenvalues  $1, \dots, 29$ , behavior of Lanczos iteration is shown below

## Jacobi Method

One of oldest methods for computing eigenvalues is Jacobi method, which uses similarity transformation based on plane rotations

Sequence of plane rotations chosen to annihilate symmetric pairs of matrix entries, eventually converging to diagonal form

Choice of plane rotation slightly more complicated than in Givens method for QR factorization

To annihilate given off-diagonal pair, choose  $c$  and  $s$  so that

$$\mathbf{J}^T \mathbf{A} \mathbf{J} = \begin{bmatrix} c & -s \\ s & c \end{bmatrix} \begin{bmatrix} a & b \\ b & d \end{bmatrix} \begin{bmatrix} c & s \\ -s & c \end{bmatrix} =$$

$$\begin{bmatrix} c^2a - 2csb + s^2d & c^2b + cs(a - d) - s^2b \\ c^2b + cs(a - d) - s^2b & c^2d + 2csb + s^2a \end{bmatrix}$$

is diagonal

## Jacobi Method, continued

Transformed matrix diagonal if

$$c^2b + cs(a - d) - s^2b = 0$$

Dividing both sides by  $c^2b$ , we obtain

$$1 + \frac{s}{c} \frac{(a - d)}{b} - \frac{s^2}{c^2} = 0$$

Making substitution  $t = s/c$ , we get quadratic equation

$$1 + t \frac{(a - d)}{b} - t^2 = 0$$

for tangent  $t$  of angle of rotation, from which we can recover  $c = 1/(\sqrt{1 + t^2})$  and  $s = c \cdot t$

Advantageous numerically to use root of smaller magnitude

## Example: Plane Rotation

Consider  $2 \times 2$  matrix

$$\mathbf{A} = \begin{bmatrix} 1 & 2 \\ 2 & 1 \end{bmatrix}$$

Quadratic equation for tangent reduces to  $t^2 = 1$ , so  $t = \pm 1$

Two roots of same magnitude, so we arbitrarily choose  $t = -1$ , which yields  $c = 1/\sqrt{2}$  and  $s = -1/\sqrt{2}$

Resulting plane rotation  $\mathbf{J}$  gives  $\mathbf{J}^T \mathbf{A} \mathbf{J} =$

$$\begin{bmatrix} 1/\sqrt{2} & 1/\sqrt{2} \\ -1/\sqrt{2} & 1/\sqrt{2} \end{bmatrix} \begin{bmatrix} 1 & 2 \\ 2 & 1 \end{bmatrix} \begin{bmatrix} 1/\sqrt{2} & -1/\sqrt{2} \\ 1/\sqrt{2} & 1/\sqrt{2} \end{bmatrix} \\ = \begin{bmatrix} 3 & 0 \\ 0 & -1 \end{bmatrix}$$

## Jacobi Method, continued

Starting with symmetric matrix  $A_0 = A$ , each iteration has form

$$A_{k+1} = J_k^T A_k J_k,$$

where  $J_k$  is plane rotation chosen to annihilate a symmetric pair of entries in  $A_k$

Plane rotations repeatedly applied from both sides in systematic sweeps through matrix until off-diagonal mass of matrix reduced to within some tolerance of zero

Resulting diagonal matrix orthogonally similar to original matrix, so diagonal entries are eigenvalues, and eigenvectors given by product of plane rotations

## **Jacobi Method, continued**

Jacobi method reliable, simple to program, and capable of high accuracy, but converges rather slowly and difficult to generalize beyond symmetric matrices

Except for small problems, more modern methods usually require 5 to 10 times less work than Jacobi

One source of inefficiency is that previously annihilated entries can subsequently become nonzero again, thereby requiring repeated annihilation

Newer methods such as QR iteration preserve zero entries introduced into matrix

### Example: Jacobi Method

$$\text{Let } \mathbf{A}_0 = \begin{bmatrix} 1 & 0 & 2 \\ 0 & 2 & 1 \\ 2 & 1 & 1 \end{bmatrix}$$

First annihilate (1,3) and (3,1) entries using rotation

$$\mathbf{J}_0 = \begin{bmatrix} 0.707 & 0 & -0.707 \\ 0 & 1 & 0 \\ 0.707 & 0 & 0.707 \end{bmatrix}$$

to obtain

$$\mathbf{A}_1 = \mathbf{J}_0^T \mathbf{A}_0 \mathbf{J}_0 = \begin{bmatrix} 3 & 0.707 & 0 \\ 0.707 & 2 & 0.707 \\ 0 & 0.707 & -1 \end{bmatrix}$$

## Example Continued

Next annihilate (1,2) and (2,1) entries using rotation

$$\mathbf{J}_1 = \begin{bmatrix} 0.888 & -0.460 & 0 \\ 0.460 & 0.888 & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

to obtain

$$\mathbf{A}_2 = \mathbf{J}_1^T \mathbf{A}_1 \mathbf{J}_1 = \begin{bmatrix} 3.366 & 0 & 0.325 \\ 0 & 1.634 & 0.628 \\ 0.325 & 0.628 & -1 \end{bmatrix}$$

Next annihilate (2,3) and (3,2) entries using rotation

$$\mathbf{J}_2 = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0.975 & -0.221 \\ 0 & 0.221 & 0.975 \end{bmatrix}$$

to obtain

$$\mathbf{A}_3 = \mathbf{J}_2^T \mathbf{A}_2 \mathbf{J}_2 = \begin{bmatrix} 3.366 & 0.072 & 0.317 \\ 0.072 & 1.776 & 0 \\ 0.317 & 0 & -1.142 \end{bmatrix}$$

## Example Continued

Beginning new sweep, again annihilate (1,3) and (3,1) entries using rotation

$$\mathbf{J}_3 = \begin{bmatrix} 0.998 & 0 & -0.070 \\ 0 & 1 & 0 \\ 0.070 & 0 & 0.998 \end{bmatrix}$$

to obtain

$$\mathbf{A}_4 = \mathbf{J}_3^T \mathbf{A}_3 \mathbf{J}_3 = \begin{bmatrix} 3.388 & 0.072 & 0 \\ 0.072 & 1.776 & -0.005 \\ 0 & -0.005 & -1.164 \end{bmatrix}$$

Process continues until off-diagonal entries reduced to as small as desired

Result is diagonal matrix orthogonally similar to original matrix, with the orthogonal similarity transformation given by product of plane rotations

## Bisection or Spectrum-Slicing

For real symmetric matrix, can determine how many eigenvalues are less than given real number  $\sigma$

By systematically choosing various values for  $\sigma$  (*slicing spectrum at  $\sigma$* ) and monitoring resulting count, any eigenvalue can be isolated as accurately as desired

For example, symmetric indefinite factorization  $\mathbf{A} = \mathbf{LDL}^T$  makes *inertia* (numbers of positive, negative, and zero eigenvalues) of symmetric matrix  $\mathbf{A}$  easy to determine

By applying factorization to matrix  $\mathbf{A} - \sigma\mathbf{I}$  for various values of  $\sigma$ , individual eigenvalues can be isolated as accurately as desired using interval bisection technique

## Sturm Sequence

Another spectrum-slicing method for computing individual eigenvalues is based on *Sturm sequence* property of symmetric matrices

Let  $\mathbf{A}$  be symmetric matrix and let  $p_r(\sigma)$  denote determinant of leading principal minor of order  $r$  of  $\mathbf{A} - \sigma \mathbf{I}$

Then zeros of  $p_r(\sigma)$  strictly separate those of  $p_{r-1}(\sigma)$ , and number of agreements in sign of successive members of sequence  $p_r(\sigma)$ , for  $r = 1, \dots, n$ , equals number of eigenvalues of  $\mathbf{A}$  strictly greater than  $\sigma$

Determinants  $p_r(\sigma)$  easy to compute if  $\mathbf{A}$  transformed to tridiagonal form before applying Sturm sequence technique

## Divide-and-Conquer Method

Another method for computing eigenvalues and eigenvectors of real symmetric tridiagonal matrix is based on divide-and-conquer strategy

Express symmetric tridiagonal matrix  $T$  as

$$T = \begin{bmatrix} T_1 & O \\ O & T_2 \end{bmatrix} + \beta uu^T$$

Can now compute eigenvalues and eigenvectors of smaller matrices  $T_1$  and  $T_2$

To relate these back to eigenvalues and eigenvectors of original matrix requires solution of *secular equation*, which can be done reliably and efficiently

Applying this approach recursively yields divide-and-conquer algorithm for symmetric tridiagonal eigenproblems

## Relatively Robust Representation

With conventional methods, cost of computing eigenvalues of symmetric tridiagonal matrix is  $\mathcal{O}(n^2)$ , but if orthogonal eigenvectors are also computed, then cost rises to  $\mathcal{O}(n^3)$

Another possibility is to compute eigenvalues first at  $\mathcal{O}(n^2)$  cost, and then compute corresponding eigenvectors separately using inverse iteration with computed eigenvalues as shifts

Key to making this idea work is computing eigenvalues and corresponding eigenvectors to very high relative accuracy so that expensive explicit orthogonalization of eigenvectors is not needed

RRR algorithm exploits this approach to produce eigenvalues *and* orthogonal eigenvectors at  $\mathcal{O}(n^2)$  cost

## Generalized Eigenvalue Problems

Generalized eigenvalue problem has form

$$Ax = \lambda Bx,$$

where  $A$  and  $B$  are given  $n \times n$  matrices

If either  $A$  or  $B$  is nonsingular, then generalized eigenvalue problem can be converted to standard eigenvalue problem, either

$$(B^{-1}A)x = \lambda x \quad \text{or} \quad (A^{-1}B)x = (1/\lambda)x$$

This is not recommended, since it may cause

- loss of accuracy due to rounding error
- loss of symmetry if  $A$  and  $B$  are symmetric

Better alternative for generalized eigenvalue problems is QZ algorithm

## QZ Algorithm

If  $A$  and  $B$  are triangular, then eigenvalues are given by  $\lambda_i = a_{ii}/b_{ii}$ , for  $b_{ii} \neq 0$

QZ algorithm reduces  $A$  and  $B$  simultaneously to upper triangular form by orthogonal transformations

First,  $B$  is reduced to upper triangular form by orthogonal transformation from left, which is also applied to  $A$

Next, transformed  $A$  is reduced to upper Hessenberg form by orthogonal transformation from left, while maintaining triangular form of  $B$ , which requires additional transformations from right

Finally, analogous to QR iteration,  $A$  is reduced to triangular form while still maintaining triangular form of  $B$ , which again requires transformations from both sides

## **QZ Algorithm, continued**

Eigenvalues can now be determined from mutually triangular form, and eigenvectors can be recovered from products of left and right transformations, denoted by  $Q$  and  $Z$

## Computing SVD

Singular values of  $\mathbf{A}$  are nonnegative square roots of eigenvalues of  $\mathbf{A}^T \mathbf{A}$ , and columns of  $\mathbf{U}$  and  $\mathbf{V}$  are orthonormal eigenvectors of  $\mathbf{A} \mathbf{A}^T$  and  $\mathbf{A}^T \mathbf{A}$ , respectively

Algorithms for computing SVD work directly with  $\mathbf{A}$ , however, without forming  $\mathbf{A} \mathbf{A}^T$  or  $\mathbf{A}^T \mathbf{A}$ , thereby avoiding loss of information associated with forming these matrix products explicitly

SVD usually computed by variant of QR iteration, with  $\mathbf{A}$  first reduced to bidiagonal form by orthogonal transformations, then remaining off-diagonal entries annihilated iteratively

SVD can also be computed by variant of Jacobi method, which can be useful on parallel computers or if matrix has special structure
