

Great Ideas in Computing

University of Toronto CSC196
Fall 2021

Week 10: November 22-26 (2021)

Announcements

Announcements

- Quiz 1 and Assignment 2 are now graded. You have one week from the time that the quiz (respectively, the assignment) was graded and made accessible to request a regrade for any specific question(s) on the quiz (resp, assignment 2). Any requests for a regrade must be very specific as to why the request is being made.
- The next quiz is scheduled for this Friday, November 26. It will be in-person.
- The final assignment is due December 3.

This weeks agenda

Agenda

- Any comments on the HCI presentation by Professor Chevalier?
- We will finish our discussion of complexity theory, NP -completeness and the $P \neq NP$ conjecture.
- We ended the Friday, Monday, November 15 class on slide 16 with Karp's initial tree of polynomial time transformations resulting in all the problems listed being NP -complete given Cook's initial result that 3 – SAT is NP -complete.

We will begin today by restating that slide, then showing (by example) how to reduce optimization problems (and similarly finding certificates) to the corresponding decision problem.

- Then we will discuss complexity based cryptography.

A tree of reductions/transformations

Polynomial-Time Reductions

Dick Karp (1972)
1985 Turing Award

Some comments on the problems in the tree of *NP*-complete problems

Polynomial time transformations are algorithms and some are “easy” and some can be very difficult to derive and prove that the transformation $h()$ satisfies what is needed for a poly time transformation \leq_{trans}^{poly} .

I posted on quercus a link to a video by David Scot Taylor at San Jose State University that explains very nicely some polynomial time transformations.

I mainly expect you to understand the definitions and their significance. If anything, I would only ask you to derive a very simple transformation.

Note that some problems come from different problem domains. Yet they are all equivalent wrt \leq_{trans}^{poly}

A “small change” in a problem can change it from polynomial time to *NP*-complete. For example

- 2 – SAT $\in P$ and 3 – SAT is *NP*-complete.
- 2 – vertexcolour $\in P$ and 3 – vertexcolour is *NP*-complete.

Optimization problems

Each of these problems has an associated optimization problem. For example, the *Vertex-Cover* problem is usually expressed as the following optimization problem:

Given a graph $G = (V, E)$, find a minimum size vertex cover for G ; that is, a subset $V' \subset V$ such that for every edge $e = (u, v) \in E$, either $u \in V'$ or $v \in V'$. This is the inclusive “or” so that it is possible that both u, v are in V' .

If we can solve the optimization problem efficiently, we can immediately solve the decision problem. **Does everyone understand this?**

What is not as immediate, is the fact that if we can solve the *Vertex-Cover* decision problem then we can solve the *Vertex-Cover* optimization problem.

We would do this by first determining (using the decision problem) the size of the minimum vertex cover. **Does everyone see how to do this?**

The vertex-cover optimization problem continued

Suppose k is the size of the minimum vertex cover. We then iteratively decide for each vertex v , whether or not we can include $v \in V'$. That is, we determine if we can remove v and all its adjacent edges and ask if the resulting graph \tilde{G} has a vertex cover of size $k - 1$. If v cannot be in the minimum vertex cover then we go on to look at another vertex.

Note that while we can “probably” restrict attention to \leq_{Karp} polynomial time transformations for the purpose of showing new problems are NP -complete, we are using the more general \leq_{Cook} polynomial time reductions to reduce the optimization problem to the decision problem.

Another conjecture: $NP \neq \text{co-NP}$

FACT: If L is NP -complete wrt \leq_{Karp} then $\bar{L} \in NP$ if and only if $NP = \text{co-NP}$

There is another widely believed conjecture again based on the inability of experts to show that $\bar{L} \in NP$ for any NP -complete problem which states that $NP \neq \text{co-NP}$. For example, as stated before, we do not believe there is a “short” certificate for showing that a graph does *not* have a Hamiltonian cycle.

As I mentioned before, we believe factoring integers is not polynomial time computable. In fact, there is a sense in which we believe it is not polynomial time computable “on average” (whereas the basic theory of NP completeness is founded on worst case analysis).

Surprisingly, co-FACTOR is in NP . That is, given an input (N, k) , we can provide a certificate verifying that N does *not* have a proper factor $m \leq k$.

Since co-FACTOR is in NP , and we conjecture that $NP \neq \text{co-NP}$, this leads us then to believe that FACTOR is in $NP \setminus P$ but *not* NP -complete.

Returning to the two different reductions

As far as I know, there is no proof that the two reductions are different but there is good reason to believe that they are different in general.

- Clearly $\bar{A} \leq_{Cook} A$ for any language A .
- $A \leq_{Karp} B$ and $B \in NP$ implies $A \in NP$.
- Hence our assumption that $NP \neq co - NP$ implies that we *cannot* have $\bar{A} \leq_{Karp} A$ for any NP -complete A .

On the other hand as far as I know all known NP complete problems can be shown to be complete using transformations \leq_{Karp} .

I know of no compelling evidence that general reductions and transformations are different when restricted to the class NP .

NOTE: The general reduction concept makes sense when reducing say a search or optimization problem to a decision problem (and indeed this is what said about *Vertex-Cover* and we will be doing next for *SAT*). On the other hand, transformations are only about decision problems (i.e., languages).

Finding a certificate for an NP -complete problem

One might wonder if we can always efficiently *find* a certificate if we can decide whether or not a certificate exists. In fact, for NP -complete problems we can (Cook) reduce finding a certificate to deciding if a certificate exists.

Fact Let L be a NP -complete problem. We can prove that for every YES input instance x (where we know that a certificate exists wrt some verification predicate) that a certificate can be computed in polynomial time assuming we can solve the decision problem in polynomial time.

Of course, we do not believe the decision problem can be solved in polynomial time so this is just a claim that it is sufficient to just focus on the decision problem.

As an example, consider SAT and suppose F is satisfiable. That means we can set each propositional variable (to TRUE or FALSE) so that the formula evaluates to TRUE. **So how do we find a satisfying truth assignment for F ?**

Finding a satisfying assignment for a formula F assuming $P = NP$

Once we assume $P = NP$, we would know that the decision problem for SAT is satisfiable. So we would first test if the given formula F is satisfiable. If so, we can construct a satisfying assignment one variable at a time. Consider the following example of a 3-SAT formula:

$$F = (\bar{x}_1 \vee x_2) \wedge (\bar{x}_2 \vee x_3) \wedge (\bar{x}_3 \vee \bar{x}_1 \wedge (x_1 \vee x_2 \vee x_3))$$

Now since F is satisfiable, there must be some way to set (say) x_1 to either TRUE or FALSE so that the resulting formula still is satisfiable.

If we set x_1 to TRUE, then the resulting formula $F' = F|_{x_1=TRUE}$ will become FALSE so it must be that x_1 is FALSE in any satisfying assignment.

How would we know that $F' = F|_{x_1 = TRUE}$ is not satisfiable?

Finding a satisfying assignment for a formula F assuming $P = NP$

Once we assume $P = NP$, we would know that the decision problem for SAT is satisfiable. So we would first test if the given formula F is satisfiable. If so, we can construct a satisfying assignment one variable at a time. Consider the following example of a 3-SAT formula:

$$F = (\bar{x}_1 \vee x_2) \wedge (\bar{x}_2 \vee x_3) \wedge (\bar{x}_3 \vee \bar{x}_1 \wedge (x_1 \vee x_2 \vee x_3))$$

Now since F is satisfiable, there must be some way to set (say) x_1 to either TRUE or FALSE so that the resulting formula still is satisfiable.

If we set x_1 to TRUE, then the resulting formula $F' = F|_{x_1=TRUE}$ will become FALSE so it must be that x_1 is FALSE in any satisfying assignment.

How would we know that $F' = F|_{x_1=TRUE}$ is not satisfiable? We would again use the decision procedure SAT applied to F' . We would continue this way to see how to set x_2, x_3 . In this example, x_2 can be set TRUE or FALSE and we would just choose one value.

Some Final comments on complexity theory

I know some (many?) students may find complexity theory and in particular NP -completeness to be difficult material especially if you have seen these concepts before.

I do think this material is fundamental to computer science (as a discipline) and computing (in terms of its impact).

Some ideas are great ideas even when we are not that aware of them. I argued that this was the case with respect to Turing's work and the von Neumann model.

The concept of NP completeness is something that algorithm designers may or may not think of routinely but at some level of understanding we do need to know that common (say optimization) problems cannot be solved efficiently for all input instances.

I mentioned that there have been many surprises in complexity theory so I again emphasize that a conjecture may guide our thinking but we always have to be aware of what has and has not been proven.

Some final comments on complexity; Can randomization help?

We should note that there are many other fundamental questions in complexity theory (in addition to the P vs NP question). One such question is [can randomization help](#). I am going to rush through these slides but just want to mention the issue of randomization.

Consider the following problem: We are *implicitly given* two multivariate polynomials $p(x_1, \dots, x_n)$ and $q(x_1, \dots, x_n)$. For example, the polynomials might be the result of a polynomial time computation using the arithmetic operations $+$, $-$, $*$. Or p and q might be the determinants of $n \times n$ matrices with entries that are linear functions of the $\{x_i\}$.

The *polynomial equivalence question* whether or not $p \equiv q$ as polynomials; that is, does $p(x_1, \dots, x_n) = q(x_1, \dots, x_n)$ for all values of the $\{x_i\}$. Lets say that the x_i are all integers or rationals.

Note that this is the same as asking whether or not $p - q \equiv \mathbf{0}$ where $\mathbf{0}$ is the zero polynomial.

Polynomial equivalence problem continued

How would you solve the *identically zero* question for a univariate polynomial (again given implicitly)?

Polynomial equivalence problem continued

How would you solve the *identically zero* question for a univariate polynomial (again given implicitly)?

Fact: A non zero univariate polynomial $p(x)$ of degree d has at most d distinct zeros. This means that if we evaluate $p(x)$ at say $t > d$ random points r_1, \dots, r_t , the probability that $p(r_i) = 0$ is at most $\frac{d}{t}$.

Schwartz-Zippel Lemma: This lemma extends the above fact to multivariate polynomials. That is,

If $p(x_1, \dots, x_n)$ is a non zero polynomial of total degree d (with coefficients in a ring or field F like the integers or rationals) then

$Prob[p(r_1, \dots, r_n) = 0] \leq \frac{d}{|S|}$ when the r_i are chosen randomly in a finite subset $S \subseteq F$.

End of Monday, November 22 class and today's agenda

We ended the rMNonday class with a rushed introduction of the issue of what can be done in randomized polynomial time.

I may have misspoken and want to clarify things this morning.

The second and final quiz is this Friday, November 26, 9-10 (full hour). The quiz will have three questions. One on search engines (two parts), one neural net question like you have done on a previous assignment, and one on fair division. I have changed what I originally intended.

After I clarify my remarks on randomized polynomial time, we begin complexity based cryptography.

Polynomial equivalence and the class RP

So to test if p is identically zero, we take $|S|$ sufficiently large (or do repeated independent trials with say $|S| = 2d$), and see if the evaluation returns a non-zero value. If $p(r_1, \dots, r_n) = 0$, we will claim that $p \equiv \mathbf{0}$. The error in this claim will be at most $\frac{d}{|S|}$ and we will only make an error if $p \neq \mathbf{0}$.

This is an example of a polynomial time randomized algorithm with 1-sided error (with say error at most $\frac{1}{2}$) and RP is the class of languages that have such an algorithm.

In fact the error can be as big as $1 - \frac{1}{n^k}$ for any fixed k as we can do polynomially many repeated trials to reduce the error probability using the fact that $(1 - 1/t)^t \rightarrow \frac{1}{e}$ as $t \rightarrow \infty$.

Open question: Is $RP = P$? As a specific example, is the polynomial equivalence problem in P ?

RP and BPP

Surprisingly, some prominent complexity theorists (but not everyone) believe $P = RP$. More generally, they believe $BPP = P$ where BPP is the class of languages that can be solved by a polynomial time randomized algorithm with 2-sided error (with probability of error at most $\frac{1}{2} - \frac{1}{n^k}$).

Like RP , we can amplify the probability of a correct answer by running a polynomial number of trials and taking the “majority vote” amongst the outcomes of the individual trials.

A language in RP can be formulated so that there are many certificates and hence $RP \subseteq NP$.

One final comment about the conjecture $P \neq NP$. While we strongly believe $P \neq NP$, all is not lost if $P \neq NP$. For example, while an optimization problem it can be NP -hard to compute an *optimal solution*, for many NP -hard problems there are efficient *approximately optimal* algorithms. And many natural problems have efficient algorithms when considering restricted classes of (or distributions over) instances that tend to occur naturally.

Complexity based cryptography and Public key encryption

In our discussion of cryptography, I am relying on CSC2426F graduate course notes by Charles Rackoff. See

<http://www.cs.toronto.edu/~rackoff/2426f20/Cryptonotes.html>

I may also be using web page notes by Paul Johnson. See

<http://pajhome.org.uk/crypt/index.html>

What is *complexity based cryptography*?

We are going to explore a counter-intuitive idea: Namely, the ability to use assumptions about what *cannot* be computed efficiently (i.e., negative results) to establish positive results for applications such as pseudo-random number generators, public key cryptography, digital signatures, secret sharing, and more. These applications all fall under the general topic of complexity based cryptography. Our focus will be on pseudo-random number generators (PRNG) and public key cryptography (PKC).

Randomization is necessary

Before we begin, we should note that *randomization* is almost always necessary for cryptography. This is not the first time we have encountered the need for randomization.

When have we used randomization before?

But there are applications where randomization is necessary

- Simulating stochastic events
- Hashing
- Differential Privacy
- And we can add cryptography to this list

A secure shared secret key session

In this setting, two people called A and B (sometimes referred to as Alice and Bob) have been able to share *secret key* (e.g., a secret string of bits) and will use that secret key to communicate over an insecure channel. This insecure channel can be observed or perhaps even modified by an adversary.

Figure: One-way communication. Figure taken from Rackoff notes

Shared-secret key session continued

An important consideration is how powerful is the adversary. To do things reasonably carefully, we would probably need a full graduate course on cryptography. It is difficult enough to develop the main ideas even assuming that the adversary can only eavesdrop so lets make that assumption.

In a one-way session, A has an m bit message $M = M_1M_2 \dots M_m \in \{0, 1\}^m$. (For simplicity, we are assuming that the message and the secret key have been represented as a binary strings but this is not essential.) The message is called the *plain text*.

In the shared secret key setting we are assuming the A and B have agreed upon a secret key n bit key $K = K_1K_2 \dots K_n \in \{0, 1\}^n$.

A will encode his message by a function $ENC : \{0, 1\}^m \times \{0, 1\}^n \rightarrow \{0, 1\}^*$. Here we are using the $*$ to suggest that the encoded message length can depend on the plain text message. The encoded message is called *the cypher text*.

Shared-secret key session continued

B will decode the cypher text by a function

$$DEC : \{0, 1\}^* \times \{0, 1\}^n \rightarrow \{0, 1\}^m.$$

What properties do we want from the exchange?

Shared-secret key session continued

B will decode the cypher text by a function

$$DEC : \{0, 1\}^* \times \{0, 1\}^n \rightarrow \{0, 1\}^m.$$

What properties do we want from the exchange?

- **Privacy:** The adversary should not learn anything “signifiicant” about the plain text. What does the adversary know in advance about the plain text?
- **Correctness:** B should be able to correctly decode the message. That is $DEC(ENC(M, K), K) = M$ for all M and K .

We might ask what is *perfectly secure session*? In the Rackoff notes #0, there are three equivalent definitions. Let’s just use the first one. For a given plain text message M , a uniformly random key K induces a distribution D_M on the cypher texts. The session is perfectly private if the distribution D_M does not depend on M .

Is a perfectly secure session attainable?

When is a perfectly secure session attainable?

Fact: A Perfectly secure session is attainable if and only if $|M| \leq |K|$.

When $|M| \leq |K|$, a *one-time pad* provides a single perfect secure session. A one-time pad is defined as follows:

$ENC(M, K) = E_1 E_2 \dots E_m$ where $E_i = M_i \oplus K_i$ for $1 \leq i \leq m$ and
 $DEC(E, K) = E_1 \oplus K_1, \dots, E_m \oplus K_m$.

Note that \oplus , the exclusive OR, flips a bit.

Warning: Never use an old key for a new purpose. For example, we cannot securely send two m bit messages with the same m bit key.

So how are we going to continually generate random private keys (or long keys that can be partitioned into session keys) for different people to communicate? We cannot assume people can get together physically and even so how can they generate truly random strings of bits?

Complexity based assumptions; public key cryptography

The one-time pad does not need any assumptions and an adversary can have unlimited computational power and still cannot gain any information from a one-time pad. But as we noted, a one-time pad is not a very practical solution especially for frequent transactions in e-commerce.

The major application of *public key cryptography* is to enable key exchange. For public key cryptography (and almost all cryptographic applications) we will need complexity assumptions stronger than (but still widely accepted) $P \neq NP$. To make public key systems practical we will also need some sort of trusted public key infrastructure.

We will just discuss one well known public key system, *RSA*, which is based on the assumption that factoring large integers is hard even in some average sense (rather than worst case sense). This is a much stronger assumption than $P = NP$ since $P = NP$ would allow us to factor integers in polynomial time.

The basic idea of public key encryption

Public key encryption was introduced by Diffie and Hellman, and a particular method (RSA) was created by Rivest, Shamir and Adelman.

The basic idea is that in order for Alice (or anyone) to send Bob a message, Bob is going to create two related keys, a public key allowing Alice to send an encrypted message to Bob, and a private key that allows Bob to decrypt Alice's message.

Figure: Diagram of public key encryption. Figure taken from Paul Johnston notes

End of Wednesday, November 24 class

We ended the class with the idea of public key cryptography. I am leaving the remaining slides for continuity but they will again appear in the week 11 slides.

Next week we continue with a specific encoding scheme, namely RSA which I believe was the first commercially available public key encryption scheme.

There is some “basic” number theory that is needed to understand the RSA scheme and its relation to factoring. What is important for us is to just understand how Alice encrypts and Bob decrypts.

The RSA method

Bob wants to generate two keys, a public key e, N and a private key d . The claim is that it is hard on average to find d given e and N . Bob chooses $N = p \cdot q$ for two large primes p, q (which for defining “on average” may satisfy some constraint).

Bob will choose the public e such that $\gcd(e, \phi(N)) = 1$ where $\phi(N) = \phi(pq) = (p - 1)(q - 1)$. $\phi(N)$ is called the Euler totient function which is equal to the number integers less than N that are relatively prime to N . $\gcd(a, b) = 1$ means that a and b are relatively prime (i.e. have no common proper factors).

Alice encodes a message M by computing $M^e \bmod N$.

Hiding some mathematics, BOB can compute a d such that $de = 1 \bmod (p - 1)(q - 1)$ since Bob knows p and q . But without knowing p, q , finding d becomes computationally difficult.

Hiding some more mathematics, it will follow that $M^{de} = M \pmod N$ for any message M . That is, Bob decrypts a cypher text C by the function $C^d \bmod N$.

What mathematical facts do we need to know.

The main mathematical facts are :

- 1 There are sufficiently many prime numbers in any range so one can just randomly try to different numbers and test if they are prime.
- 2 $a^{\phi(N)} = 1 \pmod N$ for any a such that $\gcd(a, N) = 1$. As a special case, $a^{p-1} = 1 \pmod p$ for any prime p and a not a multiple of p . So we have $M^{(p-1)(q-1)} = 1 \pmod N$.
- 3 If $\gcd(a, b) = 1$ then there exists s and t such that $sa + tb = 1$. In the RSA algorithm, we can let $a = e$ and $b = (p-1)(q-1)$. Then s will become the d we need for decryption. That is $de + t(p-1)(q-1) = 1$.
- 4 It follows then that $M^{de} = M^{1-t(p-1)(q-1)} = M \cdot M^{-t(p-1)(q-1)} = M \pmod{(p-1)(q-1)}$.

What computational facts do we need to know?

- 1 The extended Euclidean algorithm can efficiently compute an s and t such that $sa + tb = \gcd(a, b)$
- 2 $a^k \bmod N$ can be computed efficiently for any a, k, N .
- 3 We can efficiently determine if a number p is prime.

In practice, public keys e are chosen to be reasonably small so that encryption can be made more efficient.

Note that we have been assuming that an adversary EVE (i.e., is just eavesdropping) and not changing messages. That is, EVE just wants to learn the message or something about the message. If EVE could change messages then EVE could pretend to be BOB. So one needs some sort of a public key infrastructure.

Note that if EVE knows that the message M was one a few possibilities, then EVE can try each of the possibilities; that is compute $M^e \bmod N$ for each possible M to see what message was being sent. So here is where randomness can be used. We can pad or interspers random bits in the plain text M so that the message being sent becomes some one of many random messages M' .

WARNING: Real world cryptography is sophisticated

Complexity based cryptography requires careful consideration of the definitions and what precise assumptions are being made.

Complexity based cryptography has led to many important practical protocols and there are a number of theorems. Fortunately, many complexity assumptions turn out to be equivalent.

In the Rackoff notes, the following theorem is stated as the fundamental theorem of cryptography. (To make this result precise, one needs precise definitions which we are omitting.)

Theorem: The following are equivalent:

- It is possible to do “computationally secure sessions”
- There exists pseudo-random generators; that is, create strings that computationally look random)
- There exist one way functions f ; that is functions such that $f(x)$ is easy to compute but given $f(x)$ it is hard to find a z such that $f(z) = f(x)$. Here “hard to find” means not computable in polynomial time.
- There exist computationally secure digital signature schemes.

The discrete log function

RSA is based on the assumed difficulty of factoring. Another assumption that is widely used in cryptography is the discrete log function. Again, we need some facts from number theory.

Let p be a large prime.

- \mathbb{Z}_p^* denotes the set of integers $\{1, 2, \dots, p-1\}$ under the operations of $+$, $-$, $\cdot \pmod p$ is a *field*. In particular, for every $a \in \mathbb{Z}_p^*$, there exists a $b \in \mathbb{Z}_p^*$ such that $a \cdot b = 1$; i.e., $b = a^{-1} \pmod p$.
- Moreover, \mathbb{Z}_p^* is *cyclic*. That is, there exists a $g \in \mathbb{Z}_p^*$ such that $\{1, g, g^2, g^3, \dots, g^{p-2}\} \pmod p = \mathbb{Z}_p^*$. Recall, as a special case of the Euler totient function, $a^{p-1} = 1 \pmod p$.

The assumption is that given $(g, p, g^x \pmod p)$, it is computationally difficult to find x . This is another example (factoring can also be an example) of a *one-way function*. In fact the discrete log function is a *one-way permutation*.

A pseudo random generator

We started off our discussion of complexity based cryptography by noting that randomness is essential. We have also noted that it is not clear (or at what cost) one can obtain strings that “look like” truly random strings.

A pseudo random generator G is a *deterministic* function $G : \{0, 1\}^k \rightarrow \{0, 1\}^\ell$ for $\ell > k$. When ℓ is exponential in k , G is called a pseudo random function generator. For now, let's even see how to be able to have $\ell = k + 1$.

The random input string $s \in \{0, 1\}^k$ is called the seed and the goal is that $r = G(s)$ should be “computationally indistinguishable” from a truly random string in $t = \{0, 1\}^\ell$. This means that no polynomial time algorithm can distinguish between r and t with probability better than $\frac{1}{2} + \epsilon$ for any $\epsilon > 0$. (Here I am being sloppy about the quantification but hopefully the idea is clear.)

A pseudo random generator continued

On the previous slide there was a claim that having a pseudo random generator is equivalent to having a one-way function.

How can we use (for example, the assumption that the discrete log function is a one-way function) to construct a pseudo random generator with $\ell = k + 1$.

The Blum-Micali generator. Assuming the discrete log function is a one-way function then the following is a pseudo random generator:

Let x_0 be a random seed in \mathbb{Z}_p^* by interpreting $(s_1, \dots, s_k)_2$ as a binary number mod p . Let $x_{k+1} = g^{x_k} \bmod p$. Define $s_{k+1} = 1$ if $x_k \leq \frac{p-1}{2}$.

Manuel Blum won the Turing award for his contributions to cryptography and Silvio Micali (along with Shafira Goldwasser) won the Turing award for *interactive zero knowledge proofs*. (Note: The authors on the seminal zero knowledge paper are Goldwasser, Micali, and Rackoff where I am noting that Charlie Rackoff is a UT DCS Professor Emeritus.)
