Abstraction of Source Code

(from Bandera lectures and talks)

Abstraction: the key to scaling up

Safety: The set of behaviors of the abstract system over-approximates the set of behaviors of the original system
Data Abstraction

- Data Abstraction
  - Abstraction proceeds component-wise, where variables are components

![Diagram showing data abstraction]

Data Type Abstraction

Collapses data domains via abstract interpretation:

**Code**

```c
int x = 0;
if (x == 0)
  x = x + 1;
```

**Data domains**

```
int
(n<0) : NEG
(n=0) : ZERO
(n>0) : POS
```

```
Signs
NEG | ZERO | POS
```

```
Signs x = ZERO;
if (Signs(x=ZERO))
  x = Signs(x=POS);
```
Hypothesis

Abstraction of data domains is necessary

Automated support for
- Defining abstract domains (and operators)
- Selecting abstractions for program components
- Generating abstract program models
- Interpreting abstract counter-examples

will make it possible to
- Scale property verification to realistic systems
- Ensure the safety of the verification process

Definition of Abstractions in BASL

Example: Start safe, then refine: \((\text{NEG}\cdot\text{NEG})=\text{NEG}\cdot\text{POS}\cdot\text{POS}\)
Compiling BASL Definitions

```
Compiling □ BASL □ Definitions

Compiling □ BASL □ Definitions

Interpreting Results

- For an abstracted program, a counter-example may be infeasible because:
  - Over-approximation introduced by abstraction

- Example:
  x = -2; if(x + 2 == 0) then ...
  x = NEG; if(Signs.eq(Signs.add(x,POS),ZERO)) then ...

{NEG,ZERO,POS}
```
Choose-free state space search

- **Theorem [Saidi: SAS'00]**
  Every path in the abstracted program where all assignments are deterministic is a path in the concrete program.

- **Bias the model checker**
  - to look only at paths that do not include instructions that introduce non-determinism

- **JPF model checker modified**
  - to detect non-deterministic choice (i.e. calls to Bandera.choose()); backtrack from those points

Choice-bounded Search

[Diagram of state space search with nodes and paths]
Counter-example guided simulation

- Use abstract counter-example to guide simulation of concrete program
- Why it works:
  - Correspondence between concrete and abstracted program
  - Unique initial concrete state

Example of Abstracted Code
Example of Abstracted Code

Hybrid Approach
Property Abstraction

Properties are temporal logic formulas, written in negational normal form. Abstract propositions under-approximate the truth of concrete propositions.

Examples:
- Invariance property: \( \square (x > -1) \)
- Abstracted to: \( \square ((x = \text{zero}) \lor (x = \text{pos})) \)

- Invariance property: \( \square (x > -2) \)
- Abstracted to: \( \square ((x = \text{zero}) \lor (x = \text{pos})) \)

If the abstract property holds on the abstract system, then the original property holds on the original system.
Predicate Abstraction

- Predicate Abstraction
  - Use a boolean variable to hold the value of an associated predicate that expresses a relationship between variables.

An Example

```c
unit:
  x := 0;  y := 0;  0 := 1;
goto zero;

zero:
  ss00t (0 = 1);
  x := (x + 1);
  y := (y + 1);
  if (x = 0) then z1 := 0;  goto z0;

z1:
  0 := 1;
goto zero;

z0:
  0 := 0;
goto zero;
```

- x and y are unbounded.
- Data abstraction does not work in this case --- abstracting component-wise (per variable) cannot maintain the relationship between x and y.
- We will use predicate abstraction in this example.
**Predicate Abstraction Process**

- Add boolean variables to your program to represent current state of particular predicates
  - E.g., add a boolean variable \( \bar{x} = \bar{e} \) to represent whether the condition \( x = e \) holds or not
- These boolean variables are updated whenever program statements update variables mentioned in predicates
  - E.g., add updates to \( \bar{x} = \bar{e} \) whenever \( x \) or \( e \) or assigned

**An Example**

```plaintext
unit:
  x := 0;  z := 0;  d := 1;
goto redo;

redo:
  issuet (d = 1);
  x := (x + 1);
  d := (d + 1);
  if (x = 0) then z1 else z0;

z1:  d := 1;
goto redo;

z0:  d := 0;
goto redo;
```

- We will use the predicates listed below, and remove variables \( x \) and \( z \) since they are unbounded.
- Don’t worry too much yet about how we arrive at this particular set of predicates; we will talk a little bit about that later

<table>
<thead>
<tr>
<th>Predicates</th>
<th>Boolean Variables</th>
</tr>
</thead>
<tbody>
<tr>
<td>( \bar{z}_1: (x = 0) )</td>
<td>( \bar{z}_1: \bar{x}(x = 0) )</td>
</tr>
<tr>
<td>( \bar{z}_2: (z = 0) )</td>
<td>( \bar{z}_2: \bar{x}(z = 0) )</td>
</tr>
<tr>
<td>( \bar{z}_3: (x = (d + 1)) )</td>
<td>( \bar{z}_3: \bar{x}(x = (d + 1)) )</td>
</tr>
<tr>
<td>( \bar{z}_4: (x = 0) )</td>
<td>( \bar{z}_4: \bar{x}(x = 0) )</td>
</tr>
</tbody>
</table>

This is our new syntax for representing boolean variables that helps make the correspondence to the predicates clear.
Transforming Programs

An example of how to transform an assignment statement

Predicates

\[ [(x = 0)] \]
\[ [(y = 0)] \]
\[ [(x = (y + 1))] \]
\[ [(x = y)] \]

Assignment

Statement

The statement to the left is replaced by the statements below

Make a more compact representation using a helper function \( H \) (following SLAM notation)

State Simulation

Given a program abstracted by predicates \( E_1, \ldots, E_n \), an abstract state simulates a concrete state if \( E_i \) holds on the concrete state iff the boolean variable \([E_i]\) is true and remaining concrete vars and control points agree.

Concrete

\( (n2, [x \ 2, y \ 2, z \ 0]) \)
\( (n2, [x \ 3, y \ 3, z \ 0]) \)
\( (n2, [x \ 1, y \ 0, z \ 1]) \)
\( (n2, [x \ 3, y \ 3, z \ 1]) \)

Simulates

Abstract

\( (n2, [x=0] \quad \text{False,} \]
\( [y=0] \quad \text{False,} \]
\( [x=(y+1)] \quad \text{False,} \]
\( [x=y] \quad \text{True,} \]
\( [x=0] \quad \text{False,} \]
\( [y=0] \quad \text{True,} \]
\( [x=(y+1)] \quad \text{True,} \]
\( [x=y] \quad \text{False,} \]
\( [z=0] \quad \text{False,} \]
\( [z=1] \quad \text{False,} \]

\( (n2, [x=0] \quad \text{False,} \]
\( [y=0] \quad \text{True,} \]
\( [x=(y+1)] \quad \text{True,} \]
\( [x=y] \quad \text{False,} \]
\( [z=1] \quad \text{False,} \]

Does not simulate
Computing Abstracted Programs

- For each statement $s$ in the original program, we need to compute a new statement that describes how the given predicates change in value due to the effects of $s$.
- To do this for a given predicate $P_{i}$, we need to know if we should set $[P_{i}]$ to true or false in the abstract target state.
- Thus, we need to know the conditions at $(n_{i}, \sigma_{i})$ that guarantee that $[P_{i}]$ will be true in the target state and the conditions that guarantee that $[P_{i}]$ will be false in the target state. These conditions will be used in the helper function $H$.

Example

- What conditions have to hold before $a$ is executed to guarantee that $x=y$ is true (false) after $a$ is executed?
  - Note: we want the least restrictive conditions
- The technical term for what we want is the “weakest pre-condition of $a$ with respect to $x=y$”

Let’s take a little detour to learn about weakest preconditions.
Floyd-Hoare Triples

A triple is a logical judgement that holds when the following condition is met:

For all states \( s \) that satisfies \( F_1 \) (i.e., \( s \in F_1 \)), if executing \( C \) on \( s \) terminates with a state \( s' \), then \( s' \in F_2 \).

Weaker/Stronger Formulas

- If \( F' \sqsubseteq F \) (\( F' \) implies \( F \)), we say that \( F \) is weaker than \( F' \).
- Intuitively, \( F' \) contains as least as much information as \( F \) because whatever \( F \) says about the world can be derived from \( F' \).
- Intuitively, stronger formulas impose more restrictions on states.

Thinking in terms of sets of states...

Let

\[
S_F = \{ s | s \in F \} \\
S_{F'} = \{ s | s \in F' \}
\]

Note that \( S_{F'} \sqsubseteq S_F \) since \( F' \) imposes more restrictions than \( F \).

Question: what formula is the weakest of all? (In other words, what formula describes the largest set of states? What formula imposes the least restrictions?)
Weakness Preconditions

The \textit{weakest precondition} of a command $C$ with respect to $F_2$ (denoted $WP(C,F_2)$) is a formula $F_1$ such that:

$\{F_1\} C \{F_2\}$

and for all other $F'_1$ such that $\{F'_1\} C \{F_2\}$,

$F'_1 \not\preceq F_1$ (i.e., $F_1$ is weaker than $F'_1$).

- This notion is useful because it answers the question: “what formula $F_1$ captures the fewest restrictions that I can impose on a state $s$ so that when $s = [[C]]s$ then $s' \not\preceq F_2$?”
- $WP$ is interesting for us when calculating predicate abstractions because for a given command $C$ and boolean variable $[P]$, we want to know the least restrictive conditions that have to hold before $C$ so that we can conclude that $P$ is definitely true (false) after executing $C$.

Calculating Weakest Preconditions

Calculating $WP$ for assignments is easy:

$$WP(x := e, F) = F[x \leftarrow e]$$

- Intuition: $x$ is going to get a new value from $e$, so if $F$ has to hold after $x := e$, then $F[x \leftarrow e]$ is required to hold before $x := e$ is executed.

Examples:

<table>
<thead>
<tr>
<th>Expression</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>$WP(x := 0, x = y)$</td>
<td>$(x = y)[x \leftarrow 0]$</td>
</tr>
<tr>
<td>$WP(x := 0, x = y + 1)$</td>
<td>$(x = y + 1)[x \leftarrow 0]$</td>
</tr>
<tr>
<td>$WP(x := x + 1, x = y + 1)$</td>
<td>$(x = y + 1)[x \leftarrow x + 1]$</td>
</tr>
</tbody>
</table>
Calculating Weakest Preconditions

Calculating WP for other commands (state transformers):

\[
\begin{align*}
WP(\text{skip}, F) &= F \\
WP(\text{assert } e, F) &= e \land F (\neg e \land F) \\
WP(\text{assume } e, F) &= e \land F (\neg e \land F)
\end{align*}
\]

- Skip: since the store is not modified, then F will hold afterward iff it holds before.
- Assert and Assume: even though we have a different operational interpretation of assert and assume in the verifier, the definition of WP of these rely on the fact that we assume that if an assertion or assume condition is violated, it's the same as the command "not completing". Note that if \( e \) is false, then the triple \( \{ \neg e \land F \} \) assert \( e \) \((F)\) always holds since the command never completes for any state.

Assessment

Intuition:

<table>
<thead>
<tr>
<th>Source Program</th>
<th>Abstracted Program</th>
</tr>
</thead>
<tbody>
<tr>
<td>Assignment statement ( C )</td>
<td>Atomic (</td>
</tr>
<tr>
<td>But what’s wrong with this?</td>
<td>Assignment to each boolean variable ([P_i]) where each assignment has the form</td>
</tr>
<tr>
<td>[ P_i ] := ( P_0(P(P(\cdots P(P_1)))\cdots) ]</td>
<td></td>
</tr>
</tbody>
</table>

Answer: the predicates \( P_i \) refer to concrete variables, and the entire purpose of the abstraction process is to remove those from the program. The point is that the conditions in the ‘H’ function should be stated in terms of the boolean variables \([P_i]\) instead of the predicates \( P_i \).
### Assessment

- In the case of $x := 0$ and the predicate $x = y$, we have

\[
\begin{align*}
WP(x := 0, \ x=y) &= (0=y) \\
WP(x := 0, \ !x=y) &= !(0=y)
\end{align*}
\]

- In this case, the information in the predicate variables is enough to decide whether $0=y$ holds or not. That is, we can simply generate the assignment statement

\[
\circ(x=\circ) := \circ(\circ(\circ = 0) \circ \circ \circ(0=0) \circ);
\]

---

### Assessment

- In the case of $x := 0$ and the predicate $x = (y+1)$, we have

\[
\begin{align*}
WP(x := 0, \ (x=y+1)) &= (0=y+1) \\
WP(x := 0, \ !(x=y+1)) &= !(0=y+1)
\end{align*}
\]

- In this case, we don’t have a predicate variable $[0=y+1]$.

- We must consider combinations of our existing predicate variables that imply the conditions above. That is, we consider *stronger (more restrictive, less desirable but still useful)* conditions formed using the predicate variables that we have.
What Are Appropriate Predicates?

- In general, a difficult question, and subject of much research
- Research focuses on automatic discovery of predicates by processing (infeasible) counterexamples
- If a counterexample is infeasible, add predicates that allow infeasible branches to be avoided

Some general heuristics that we will follow

- Use the predicates A mentioned in property P, if variables mentioned in predicates are being removed by abstraction
  - At least, we want to tell if our property predicates are true or not
- Use predicates that appear in conditionals along “important paths”
  - E.g., \((x = 0)\)
- Predicates that allow predicates above to be decided
  - E.g., \((x = 0) \land (y = 0) \land (x = (y + 1))\)
Interpreting Results

Example of Infeasible Counter-example

```
010: if (foo + bar > 0)
   then
     assert(foo);
   else
     assert(bar);
010: assert(0);
```

```
010: if (signs > 0)
   then
     assert(0);
   else
     assert(NEGPOS);
010: assert(0);
```
